We present a detailed description of two-band quasi-two-dimensional metals with s-wave superconducting (SC) and antiferromagnetic spin-density-wave (SDW) correlations. We present a general approach and use it to investigate the influence of the difference between the shapes and the areas of the two Fermi surfaces on the phase diagram. In particular, we determine the conditions for the coexistence of SC and SDW orders at different temperatures and dopings. We argue that a conventional s-wave SC order coexists with SDW order only at very low $T$ and in a very tiny range of parameters. An extended s-wave superconductivity, for which SC gap changes sign between the two bands, coexists with antiferromagnetic SDW over a much wider range of parameters and temperatures but even for this SC order the regions of SDW and SC can still be separated by a first-order transition. We show that the coexistence range becomes larger if SDW order is incommensurate. We apply our results to iron-based pnictide materials, in some of which coexistence of SDW and SC orders has been detected.

DOI: 10.1103/PhysRevB.81.174538

I. INTRODUCTION

Discovery of new magnetically active superconductors, iron pnictides, based on FeAs (Refs. 1 and 2) or Fe(Se,S,Te) (Refs. 3 and 4) has further invigorated the on-going discussion about coexistence of different ordered electronic states in metals.\(^5\) In itinerant electrons systems, the interactions that lead to formation of superconducting (SC) and magnetic spin-density-wave (SDW) orders, “pull” and “push” the same particles, and as a result, influence each other. In particular, two orders may support each other and lead to homogeneous local coexistence of SC and SDW states; or one of them may completely suppress the other order, resulting in a state with spatially separated regions of “pure” SDW or SC orders. The transitions between various states may also be either continuous (second order) or abrupt (first order). The outcome of this interplay depends critically on a number of parameters: properties of the interactions, such as symmetry of SC pairing, their relative strengths, and also on properties of the Fermi surface (FS), such as its shape or the density of electronic states.

In pnictides this parameter space is vast. First, these are multiband materials, with two hole pockets in the center, (0,0), and two electron pockets near $\pm \pi$,0 and $\pm \pi,0$ points of the unfolded Brillouin zone (BZ) (one Fe atom per unit cell). The shapes of quasi-two-dimensional electron pockets are quite distinct in different materials, ranging from simple circle-like types in LaOFeP,\(^9\) to cross-like electronic FS in LaOFeAs,\(^9\) to ellipses in BaFe$_2$As$_2$ (Refs. 10 and 11) and even more complex propeller-like structures in (Ba,K)Fe$_2$As$_2$ (Ref. 12) (for a descending point of view on this see Ref. 11). Hole pockets are near circular but different hole pockets in the same material usually have different sizes.

Second, multiple FSs also create a number of different possibilities\(^15,14\) for electron ordering in the form of SDW, charge-density-wave states, and various superconducting states. The SC states include (1) the conventional $s^+$-wave state that has $s$-wave symmetry in the BZ and gaps of the same sign on electron and hole FSs; (2) the extended $s^+$-state that looks as $s$ wave from a symmetry point of view but has opposite signs of the gaps on pockets at (0,0) and ($\pm \pi,0$),\(^15,18\) and (3) several SC states with the nodes in the SC gap, of both $s$-wave and $d$-wave symmetries.\(^16\)–\(^23\)

As a result of this complex environment, the interplay of magnetic and superconducting orders also shows some degree of variations. Most of parent compounds of iron pnictides are magnetically ordered. Upon doping, magnetism eventually yields to superconductivity but how this transformation occurs varies significantly between different Fe pnictides. A first-order transition between SC and SDW orders has been reported for (La,Sm)O$_{1−\delta}$Fe$_3$As$_2$\(^24\)–\(^28\) On the other hand, in electron-doped Ba(Fe$_{1−x}$Co$_x$)$_2$As$_2$ recent nuclear magnetic resonance,\(^29\)–\(^32\) specific heat, susceptibility, Hall coefficient,\(^33\) and neutron-scattering experiments\(^34\) indicate that SDW and SC phases coexist locally over some doping range. In the same 122 family, experiments on hole-doped Ba$_{1−x}$K$_x$(FeAs)$_2$ disagree with each other and indicate both coexistence\(^30\) and incompatibility\(^31\) of two orders. Isovalently doped 122 material BaFe$_2$(As$_{1−y}$P$_y$)$_2$ shows the region of coexistence.\(^34\)–\(^36\)

The goal of the present work is to understand how the system evolves from an SDW antiferromagnet to an $s^+/s^-$-wave superconductor and how this evolution depends on the shape of the FS, the strengths of the interactions, and the structure of the SC order. For this we derive and solve a set of coupled nonlinear BCS-type equations for SC and SDW order parameters and compare values of the free energy for possible phases.

We report several results. First, we find that there is much more inclination for coexistence between $s^+$ and SDW orders than between the same-sign $s^+$-wave state and SDW. In the latter case, coexistence is only possible at very low $T$ and in a very tiny range of parameters. Second, the coexistence region generally grows with increased strength of SDW coupling relative to superconducting interaction. That the coexistence is only possible when SDW transition comes first has been noticed some time ago\(^37\) and our results agree with these findings. Third, when SDW order is incommensurate, the coexistence is only possible when the following two condi-
The close connection between the coexistence of the two states and the symmetry of the SC state has been discussed earlier in the context of single-band heavy-fermion materials. This connection gives a possibility to obtain information about the pure states (e.g., about the structure of the SC gap) from experimental investigations of the SC-SDW interplay, as it has been recently suggested.

The structure of the paper is as follows. In the next section we define the model and derive generic equations for the SDW and SC order parameters and an expression for the free energy. Then we simplify these formulas for the case of a small splitting between hole and electron FSs and utilize them in Secs. III–V. In Sec. III we focus on a pure SDW state, with special attention given to the interplay between ellipticity of the FS and the incommensuration of the SDW order. In the next two sections we discuss possible coexistence of SDW and SC states: in Sec. IV we present numerical results obtained in a wide range of temperatures and dopings, and in Sec. V we corroborate this with the analytical consideration in the vicinity of the crossing point of SC and SDW transitions, and at $T=0$. In Sec. VI we model the case when the splitting between the two FSs is not small. We present our conclusions in Sec. VII. Some of the results reported in this work have been presented in shorter publications.

II. MODEL AND ANALYTICAL REASONING

A. General formulation

Since the basic properties of the SC and magnetic SDW interactions and their interplay should not depend on the number of bands significantly, we consider a basic model of one hole and one-electron bands. For pnictides this means that we neglect the double degeneracy of hole and electron states at the center and the corners of the Brillouin zone, which does not seem to be essential for superconducting or magnetic order.

The basic model is illustrated in Fig. 1. Electronic structure contains two families of fermions, near one-hole and one-electron bands. Such two-band structure yields the experimentally observed stripe ($\pi, 0$) or ($0, \pi$) magnetic order which in itinerant scenario appears, at least partly, due to nesting between one-hole and one-electron bands, separated by momentum ($\pi, 0$) or ($0, \pi$). Other hole and electron bands do not participate in the SDW order. We assume that SC also primarily resides on the same two FSs, at least close to the boundary of the SDW phase. The SC order parameter on the other two bands is not zero but is smaller. Once doping increases and the system moves away from SDW boundary, we expect that the magnitudes of the SC order parameter on the two electron bands should become closer to each other.

The basic Hamiltonian includes the free fermion part $\mathcal{H}_0$, and the fermion-fermion interactions in superconducting and magnetic SDW channels,

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_\Delta + \mathcal{H}_m. \quad (2.1)$$

The free fermion part of the Hamiltonian is

---

FIG. 1. (Color online) Left: electronic structure of the two-band model considered in this paper, in the unfolded Brillouin zone. The hole FS is in the center, with SC order parameter $\Delta_x$, and the electron FSs are at ($0, \pi$) and ($\pi, 0$), with SC order parameter $\Delta_f$. The magnetic order with momentum $Q_0=(0, \pi)$ hybridize hole and electron FSs separated by $Q_0$, but leaves FSs at $(\pi, 0)$ intact. Right: by doping or pressure one may adjust the size and shape of hole and electron bands, and also SDW order parameter can be incommensurate, with momentum $Q_0+\mathbf{q}$. These effects are described by FS detuning parameter, $\delta_{kq}=(\xi_h(k+q)+\xi_f(k))/2$. 

(c) The SDW phase at low $T$ can be a metal with rather large Fermi surfaces, yet SC order does not develop. This is the case when SC order is $s^\pm$, Fig. 14.
where creation/annihilation $c^\dagger$, $c$ operators correspond to fermions near the central hole pocket $(0,0)$, and $f$ operators describe fermions near the electron pocket at $Q_0=(0,\pi)$ and the fermion dispersions near the pockets are

$$\xi_f(k) = \mu_f - \frac{k^2}{2m_f} + \frac{k^2}{2m_f} \xi_{k'f}. \tag{2.3}$$

The momenta $k$ are measured from the center of the BZ and $k'$ are deviations from $Q_0$. We assume an inversion symmetry, $\xi_{c,f}(k) = \xi_{c,f}(k)$.

The pairing interaction consists of many different pair scattering terms but the most important one is the pair hopping between holes and electron pockets,$^{13,22}$

$$\mathcal{H}_A = \sum_{k,p} V_{abg'}(k,p) c^{\dagger}_{k'c} c^g_{-p'b} f_{pa'} + \text{h.c.} \tag{2.4}$$

For definiteness, we consider SC interaction only in the singlet channel, i.e.,

$$V_{abg'}(k,p) = V_{k,p}^{SC}(i\sigma^\alpha)^{a\dagger g'}_{b\dagger \alpha'} \tag{2.5}$$

The magnetic interaction between fermions is

$$\mathcal{H}_m = -\sum_{\lambda} \sum_{p'} V_{abg'}^{SDW}(p'k;k') \left( f^{\dagger}_{p'a} c^g_{k'b} f_{k'a'} \right) + \left( f^{\dagger}_{k'a} c^g_{k'b} f_{p'a'} \right) \tag{2.6}$$

where we symmetrized the expression with respect to particle hopping between $(0,0)-(0,\pi)$ and $(0,0)-(0,\pi)$ pockets for later convenience. We take the interaction matrix in a simple form

$$V_{abg'}^{SDW}(p'k;k') = V_{k,p}^{SDW} \left( \sigma_{ab} \cdot \sigma^{g'}_{b\dagger \alpha'} \right) \tag{2.7}$$

with a constant $V_{k,p}^{SDW}$.

The evolution of the interaction couplings with energy was considered in Ref.13. Here we assume that the interactions for low-energy excitations can be represented in terms of fermion couplings to order-parameter fields in the SC and SDW channels. In the spirit of BCS-type approach, we introduce the SC order parameters

$$\Delta_f(k)_{\alpha\beta} = (i\sigma^\alpha)^{a\dagger g'}_{b\dagger \alpha'} \left( f^{\dagger}_{-p'b} f_{pa'} \right), \tag{2.8a}$$

and the SDW order parameter directed along $\mathbf{m}$. We assume that SDW order parameter has a single ordering momentum $Q = Q_0 + q$ in which case it is fully specified by $(m_q)_{\alpha\beta} = (m_q)_{\alpha\beta} = (m_q)_{\alpha\beta}$. Here we assume that the interaction couplings with energy qualitatively change the phase diagram for SC and SDW

$$\mathcal{H}_m = -\sum_{\lambda} \sum_{p} m_q V_{abg'}^{SDW}(p'k;k') \left( f^{\dagger}_{p'a} c^g_{k'b} f_{k'a'} \right) + \left( f^{\dagger}_{k'a} c^g_{k'b} f_{p'a'} \right) \tag{2.8c}$$

Since $(c^g_{-p'b} f_{pa'}) \sim (m_q)_{\alpha\beta}$, the corresponding electronic magnetization,

$$\mathbf{m}(R) = \sum_{p} m_q \left( f^{\dagger}_{p'a} c^g_{k'b} f_{k'a'} \right) e^{-iQR} + \left( f^{\dagger}_{k'a} c^g_{k'b} f_{p'a'} \right) e^{-iQR} \tag{2.9}$$

is $m_q \cos QR$ for real $m_q$ and is $m_q' \cos QR - m_q' \sin QR$ for a complex $m_q = m_q + im_q'$. In principle, SDW order parameter may contain several components with different $q$, which could give rise to domainlike structures of $\mathbf{m}(R)$. For recent studies in this direction see Ref. 52. We perform the analysis of the coexistence between SC order and SDW order with a single $q$. A more general form of the SDW order should not qualitatively change the phase diagram for SC and SDW states, however this assumption requires further verifications.

Using the forms of SC and SDW order parameters, we write the free and interaction parts in quadratic forms as

$$\mathcal{H}_0 = \sum_{k} \left[ \xi_f(k) c^{\dagger}_{kc} c^k - \xi(-k) c^{\dagger}_{-k} c^k \right]$$

$$+ \left[ \xi_f(k + q) c^{\dagger}_{k+q} c^k - \xi(-k - q) c^{\dagger}_{-k-q} c^k \right] \tag{2.9}$$

$$\mathcal{H}_A = \sum_{k} \left[ \Delta_f(k) c^{\dagger}_{k} c^k + \Delta_f(-k) c^{\dagger}_{-k} c^k \right]$$

$$+ \Delta_f(k + q) c^{\dagger}_{k+q} c^k + \Delta_f(-k - q) c^{\dagger}_{-k-q} c^k \tag{2.10}$$

$$\mathcal{H}_m = \frac{1}{2} \sum_{k} \left[ m_q c^{\dagger}_{k} c^k c^{\dagger}_{k} c^{\dagger}_{-k} \right] + \left[ m_q' c^{\dagger}_{k} c^k c^{\dagger}_{-k} c^{\dagger}_{-k} \right] \tag{2.11}$$

Hamiltonian Eq. (2.1) can be represented in the matrix form

$$\mathbf{H} = \frac{1}{2} \sum_{k} \left[ \begin{array}{ccc} \xi_f(k) & \Delta_f(k) i \sigma^\alpha_{\alpha\beta} & m_q (m_q)_{\alpha\beta} \\ -\Delta_f(k) i \sigma^\alpha_{\alpha\beta} & -\xi_f(-k) & 0 \\ m_q (m_q)_{\alpha\beta} & 0 & -m_q (m_q)_{\alpha\beta} \\ m_q (m_q)_{\alpha\beta} & 0 & -m_q (m_q)_{\alpha\beta} \\ -\Delta_f(k) i \sigma^\alpha_{\alpha\beta} & -\xi_f(-k) & 0 \\ m_q (m_q)_{\alpha\beta} & 0 & -m_q (m_q)_{\alpha\beta} \end{array} \right]$$

$$= \frac{1}{2} \sum_{k} \left[ \begin{array}{ccc} \xi_f(k) & \Delta_f(k) i \sigma^\alpha_{\alpha\beta} & m_q (m_q)_{\alpha\beta} \\ -\Delta_f(k) i \sigma^\alpha_{\alpha\beta} & -\xi_f(-k) & 0 \\ m_q (m_q)_{\alpha\beta} & 0 & -m_q (m_q)_{\alpha\beta} \\ m_q (m_q)_{\alpha\beta} & 0 & -m_q (m_q)_{\alpha\beta} \end{array} \right] \tag{2.12}$$
with $\hat{\Psi}_{k\alpha} = (c_{k\alpha}^+, c_{-k\alpha}^+, f_{k\alpha}^+, f_{-k\alpha}^+)$ and $\Psi$ being its conjugated column. The two diagonal blocks of the matrix $\hat{H}_k$ correspond to a purely SC system with $\Delta_0$ and $\Delta_f$ living on two different bands, and two off-diagonal blocks contain SDW field $m_\text{q}$ that couples fermions between the two bands.

To solve this system of equations for the SC and SDW order parameters, Eq. (2.7), we define the imaginary-time Green’s function

$$
\hat{G}(k, \tau)_{\alpha\beta} = -\left\langle T_\tau \hat{\Psi}(\tau)_{k\alpha} \hat{\Psi}(0)_{k\beta} \right\rangle = \begin{pmatrix} \hat{G}_{cc} & \hat{G}_{cf} \\ \hat{G}_{fc} & \hat{G}_{ff} \end{pmatrix}, 
$$

(2.13)

which satisfies the Dyson equation,

$$
\hat{G}^{-1}(k, \epsilon_n) = i\epsilon_n - \hat{H}_k, 
$$

(2.14)

where $\epsilon_n = \pi T (2n + 1)$ are the Matsubara frequencies. The system of equations is closed by the self-consistency equations for the SC and SDW order parameters in terms of this Green’s function,

$$
\Delta_0(k) = \sum_p V^{SC}_k \sum_{\epsilon_n} \text{Tr} \left\{ (i\sigma^0)^\dagger \hat{\tau}_3 \hat{G}_{ff}(p, \epsilon_n) \right\}, 
$$

(2.15)

$$
\Delta_f(k) = \sum_p V^{SC}_k \sum_{\epsilon_n} \text{Tr} \left\{ (i\sigma^0)^\dagger \hat{\tau}_3 \hat{G}_{cc}(p, \epsilon_n) \right\}, 
$$

(2.16)

$$
m_\text{q} = -\sum_p V^{SDW}_k \sum_{\epsilon_n} \text{Tr} \left\{ (\hat{m}\sigma^0) \hat{\tau}_3 \hat{G}_{fc}(p, \epsilon_n) \right\}. 
$$

(2.17)

Henceforth we define Pauli matrices in particle-hole space, $\hat{\sigma}_{1,2,3} = (\hat{\tau}_1 \pm \hat{\tau}_2)/2$, and the following matrices in spin- and particle-hole space,

$$
\Delta = \begin{pmatrix} 0 & (\Delta i\sigma^0)_{a\beta} \\ (\Delta i\sigma^0)_{a\beta}^\dagger & 0 \end{pmatrix}, \quad \sigma_\beta = \begin{pmatrix} \sigma^0 & 0 \\ 0 & \sigma^\beta \end{pmatrix}. 
$$

(2.18)

The expressions above are valid for complex $\Delta(k)$ and $m_\text{q}$. Below, to simplify formulas, we assume that $\Delta$’s and $m_\text{q}$ are real, i.e., consider only “sinusoidal,” cosQ, variations in the SDW order parameter. To lighten the notations, we will drop the momenta arguments $(k, k + q)$ in $\hat{\xi}_{\alpha\beta}, \Delta_0, \Delta_f$ and the subscript in $m_\text{q}$ [still implying this dependence as it appears in Eq. (2.12)].

The equations for components of the Green’s function are obtained from inversion of Eq. (2.14),

$$
\hat{G}^{-1}_{cc} = \hat{G}^{-1}_{00} - m_\text{q}^2 \hat{G}_{f0}, \quad \hat{G}_{fc} = \hat{M} \hat{G}_{f0} \hat{G}_{cc}, 
$$

(2.19a)

$$
\hat{G}^{-1}_{ff} = \hat{G}^{-1}_{f0} - m_\text{q}^2 \hat{G}_{00}, 
$$

(2.19b)

with definition

$$
\begin{pmatrix} \hat{G}^{-1}_{00} - \hat{M} \\ -\hat{M} \hat{G}^{-1}_{f0} \end{pmatrix} = \begin{pmatrix} i\epsilon_n - \hat{\xi}_n \hat{\tau}_3 - \Delta_0 & -(\hat{m}\sigma_\alpha) \hat{\tau}_3 \\ -(\hat{m}\sigma_\alpha) \hat{\tau}_3 & i\epsilon_n - \hat{\xi}_n \hat{\tau}_3 - \Delta_f \end{pmatrix}. 
$$

(2.20)

To obtain Eq. (2.19) we used the fact that the magnetic matrix $\hat{M}$ commutes with purely superconducting parts, $[\hat{M}, \hat{G}_c] = [\hat{M}, \hat{G}_f] = 0$, and $\hat{M} \hat{M} = \hat{M}^2$.

The diagonal Green’s functions $\hat{G}_{c0}$ and $\hat{G}_{f0}$ are the same as in a pure superconductor, e.g.,

$$
\hat{G}_{f0}(\epsilon_n) = \frac{\hat{G}^{-1}_{00}(\epsilon_n) - \epsilon_n}{D_{f0}}, \quad D_{f0} = \epsilon_n^2 + \hat{\xi}_f^2 + \Delta_f^2. 
$$

(2.21)

where for inversion we used the relations

$$
\langle \hat{\tau}_3 \hat{\Delta} \rangle = 0, \quad \langle (\hat{m}\sigma_\alpha) \hat{\tau}_3 \hat{\Delta} \rangle = 0, \quad \hat{\Delta}^2 = \Delta_f^2. 
$$

(2.22)

which are also employed to invert $4 \times 4$ matrices for mixed SC+SDW state. For example, for $\hat{G}_{cc}$ we have

$$
\hat{G}_{cc}(\epsilon_n) = \frac{1}{\hat{G}^{-1}_{00}(\epsilon_n) - \epsilon_n m_\text{q}^2/D_{f0}}, 
$$

(2.23)

and with the above relations in mind it becomes

$$
\hat{G}_{cc} = \hat{G}^{(1)}_{cc} + \hat{G}^{(\tau_3)}_{cc} + \hat{G}^{(\Delta)}_{cc}, 
$$

(2.24a)

where

$$
\hat{G}^{(1)}_{cc} = -\frac{i\epsilon_n D_{f0} + m_\text{q}^2}{D}, 
$$

(2.24b)

$$
\hat{G}^{(\tau_3)}_{cc} = -\frac{\epsilon_n D_{f0} - \xi_f m_\text{q}^2}{D} \hat{\tau}_3, 
$$

(2.24c)

$$
\hat{G}^{(\Delta)}_{cc} = -\frac{\Delta_f D_{f0} - \Delta_0 m_\text{q}^2}{D}. 
$$

(2.24d)

The denominator

$$
D = \frac{\epsilon_n^2 (D_{f0} + m_\text{q}^2) + (\xi_f D_{f0} - \xi_s m_\text{q}^2)^2 + (\Delta_f D_{f0} - \Delta_0 m_\text{q}^2)^2}{D_{f0}} 
$$

$$
= (\epsilon_n^2 + \epsilon_c^2 + \Delta_f^2) (\epsilon_n^2 + \epsilon_c^2 + \Delta_f^2) + 2 \epsilon_c^2 (\epsilon_n^2 - \xi_f \Delta_f) + m_\text{q}^4 
$$

$$
= (\epsilon_n^2 + \epsilon_c^2 + E_0^2) (\epsilon_n^2 + E_0^2) 
$$

(2.25)

gives the energies of new excitations in the system, cf. Ref. 29. We obtained (explicitly showing $k$ and $q$ here),

$$
E_0^2 = \hat{\xi}_k q + \hat{\xi}_{kq} + m_\text{q}^2 + (\Delta_{kq}^-)^2 
$$

$$
+ (\Delta_{kq}^+)^2 \pm 2 \sqrt{m_\text{q}^2 (\Delta_{kq}^2 + \hat{\xi}_{kq}^2)} \pm (\Delta_{kq}^+ \Delta_{kq}^- + \hat{\xi}_{kq} \hat{\xi}_{kq}) 
$$

(2.26)

with

$$
\hat{\xi}_{kq} = \frac{\hat{\xi}_f (k + q) - \hat{\xi}_f (k)}{2}. 
$$

(2.27)
\[ \delta_{kq} = \frac{\xi_f(k + q) + \xi_i(k)}{2} \] (2.28)

and

\[ \Delta_{kq} = \frac{\Delta_f(k + q) - \Delta_i(k)}{2}, \] (2.29)

\[ \Delta^+_{kq} = \frac{\Delta_f(k + q) + \Delta_i(k)}{2}. \] (2.30)

The parameter \( \delta_{kq} \) describes the dispersion and the parameter \( \Delta_{kq} \) describes deviations of the electron and hole FSs from perfect nesting, as illustrated in Figs. 1 and 2. For the interband part of the Green’s function we obtain

\[ \hat{G}_{fe}(e_n) = \hat{M} \hat{G}_{ff} \hat{G}_{cc} \]

To calculate the relative stability of different states, one also needs to evaluate the free energy. We follow the Luttinger-Ward\(^{53} \) and De Dominicis-Martin\(^{54} \) method, and consider the functional\(^{55} \)

\[ F = -\frac{1}{2} Sp\{\hat{\Sigma} \hat{G} + \ln[-(ie_n - \hat{\xi}) + \hat{\Sigma}]\} + \Phi[\hat{G}], \] (2.36)

which, if minimized with respect to \( \hat{G} \), gives self-consistency equations, \( \hat{\Sigma}[\hat{G}] = 2 \delta \Phi[\hat{G}] / \delta \hat{G} \), and, if minimized with respect to \( \hat{\Sigma} \), gives the Dyson equation, Eq. (2.14). Here \( Sp \) is the trace over two fermion bands, spin, particle-hole matrix structure, and the sum over Matsubara energies and the integral over momenta, and \( \hat{\Sigma} \) is the mean-field SC and SDW order-parameter matrix,

\[ \hat{\Sigma} = \begin{pmatrix} \hat{\Delta}_c & \hat{M} \\ \hat{M} & \hat{\Delta}_f \end{pmatrix}. \] (2.37)

The functional \( \Phi[\hat{G}] \) producing the self-consistency equations is a quadratic function of \( \hat{G} \). Using the self-consistency equations one can explicitly verify that at weak coupling it can be written as \( \Phi[\hat{G}] = \frac{1}{2} Sp\{\hat{\Sigma} \hat{G} \} \). To deal with the logarithm in Eq. (2.36) one introduces a continuous variable \( \lambda \) instead of \( e_n \) differentiates the logarithmic term with respect to \( \lambda \) to obtain the Green’s function \( \hat{G}(\lambda) = (\lambda - \hat{\xi} - \hat{\Sigma})^{-1} \), and then integrates back to get the difference between a condensed state and the normal state for fixed external parameters, such as temperature or field,

\[ \Delta F(\Delta_{c,f}, m) = -\frac{1}{2} Sp\left\{ \frac{1}{2} \hat{\Sigma} \hat{G} - \int_{e_n}^{\infty} d\lambda [i \hat{G}(\lambda) - i \hat{G}^*(\lambda)] \right\}, \] (2.38)

where \( \hat{G} = \hat{G}_{fe} \) is the Green’s function in the normal state without either SC or SDW order and we used the fact that in the normal state \( \hat{\Sigma} = 0 \). Substituting into Eq. (2.38) the Green’s functions Eqs. (2.32), the self-energy Eq. (2.37), and using the self-consistency equations Eqs. (2.33)–(2.35) to eliminate the high-energy cutoffs in order to regularize the \( e_n \) summation and \( k \) integration, one obtains the most general free-energy functional for given \( \Delta_{c,f} \) and \( m \).

**B. Limit of small Fermi-surface splitting**

In principle, equations for full Green’s functions Eq. (2.32), the self-consistency equations Eqs. (2.33)–(2.35) and the free energy Eq. (2.38), completely describe the system in...
order terms, which we neglected in the last lines of Eq. (A2). These terms make hole and electron DOS different from each other, what in turn makes $|\Delta_s|$ and $|\Delta_\perp|$ nonequal, but these terms are small in $\delta_{kq}/\mu_{c,f}$ and only account for subleading terms in the free energy, $\mu_{c,f}$ are Fermi energies of electron and hole bands, Eq. (2.3).

This approximation comes at certain price. When two FSs are of very different shapes, approximating them as small deviations from a single line in $k$ space everywhere is incorrect. This is shown, for example, in Fig. 2(d), where the two FSs are quite different away from the crossing points. However in this case one realizes that if at some $k$ point the two bands are far apart, the effect of the SDW is very small, and we can approximate those FS parts as participating in SC pairing only, with little or no competition from the SDW interaction. This can be seen from Eq. (2.19) for the Green’s function. For example, for electrons near the FS of the $c$ band, $\xi_c \to 0$, $\xi_f$ is large and $\tilde{G}^{-1} = \tilde{G}^{-1}_0 + O(m^2/\xi_f)$, and the corrections due to $m$ can be neglected when we go along $c$ FS away from the region where $\xi_c = \xi_f = 0$. We will return to this issue in Sec. VI, to show that the results are qualitatively the same whether we consider large or small splitting of the FSs.

For small splitting between hole and electron Fermi surfaces, we perform $\xi$ integration analytically. For this we approximate $V_{kq}^{SC}$ by an isotropic $V^{SC}$, i.e., take angle-independent SC gap. The sign of $V^{SC}$ can be arbitrary and we consider separately the two cases:

(a) $V^{SC} > 0$: results in the $s^{++}$ state, with gaps of opposite signs for electrons and holes,

$$\Delta_f = -\Delta_\perp = \Delta \quad \text{or} \quad \Delta_\perp = 0, \quad \Delta = \Delta$$

(b) $V^{SC} < 0$: $s^{++}$ state, with the same gaps on two FSs,

$$\Delta_f = \Delta_\perp = \Delta \quad \text{or} \quad \Delta_\perp = \Delta, \quad \Delta = 0.$$  

In both cases $\Delta_\perp = 0$ and the denominator of the Green’s function can be written as

$$D = (\varepsilon_n^2 + \varepsilon_f^2)(\varepsilon_n^2 + \varepsilon_\perp^2) = (\delta_{kq}^2 + \Sigma_+^2)(\delta_{kq}^2 + \Sigma_-^2),$$

(2.39)

where

$$\Sigma_+ = \varepsilon_n^2 + \Delta^2 + m^2 - \delta_{kq}^2 \pm 2 \sqrt{m^2 \Delta^2 - \delta_{kq}^2 (\varepsilon_n^2 + \Delta^2)}$$

(2.40)

with $s=\pm 1$ ($s=-1$) corresponding to $s^{++}$ ($s^{+}$) state. Closing the integration contours over $\xi_{kq}$ in the self-consistency equations and in the free energy over the upper half-plane and counting poles at $\pm \Sigma_\pm$ we obtain

$$\frac{-s}{v^{SC}} \Delta = \pi T \sum_{|\bar{\varepsilon}_n'| < \Delta} \left( \frac{1}{\Sigma_+ + \Sigma_-} \left( 1 + \frac{\varepsilon_n^2 + \Delta^2 + \delta_{kq}^2 - s \varepsilon_\perp^2}{\Sigma_+ \Sigma_-} \right) \right), \quad \frac{1}{|v^{SC}|} = \ln \frac{1.13\Lambda}{T_c},$$

(2.41)
where angle brackets denote remaining momentum averaging over directions on the FS. \( N_F \) is the density of states at the FS, and \( v_{SDW} = N_F v_{SC} \) are the dimensionless couplings in the SC and SDW channels.\(^{13}\)

The actual coexistence of the two orders, however, is a more subtle effect and needs to be determined from the exact solution of these equations and the analysis of the free energy. The difference in excitation energies Eq. (2.26) and Eq. (2.40) between \( s^{++} \) and \( s^{+-} \) is also consistent with previous studies of \( d^- \) and \( p^- \)-wave superconductivity in heavy-fermion materials\(^{19} \) that concluded the SC states with symmetry \( PT_Q = -1 \) (e.g., \( s^{+-}, d^- \)), where \( P \) is parity \( [P \Delta(p) = \Delta(-p)] \) and \( T_Q \) is the shift by the nesting vector \( |T_Q \Delta(p) = \Delta(p+Q)| \), more likely to form coexistence with SDW than those with \( PT_Q = +1 \) (e.g., \( s^{++}, p^- \)).

We will also analyze the quasiparticle DOS, which is given by the integrals over \( \delta_{kq} \) of the diagonal components of the Green’s function. For example, for \( c \) fermions

\[
g_c(e_n, \vec{k}) = \int \frac{d^d k}{\pi} \langle c|c \rangle = -\frac{i e_n}{\sum_+ + \sum_-} \left( 1 + \frac{\epsilon_n^2 + m^2 + \Delta^2 + \delta_{kq}^2}{\sum \sum} \right),
\]

which for pure SDW state reduces to

\[
g_c(e_n, \vec{k}) = -\frac{1}{2} \sum_{\pm} \frac{i e_n \pm \delta_{kq}}{\sqrt{m^2 - (i e_n \pm \delta_{kq})^2}},
\]

and actual DOS is obtained by analytic continuation,

\[
\frac{N(e, \vec{k})}{N_F} = -\frac{\Im g_c(\epsilon, \vec{k} \rightarrow \epsilon + i 0^+, \vec{k})}{N_F} = -\frac{\Im g_c(\epsilon, \vec{k} \rightarrow \epsilon + i 0^+, \vec{k})}{N_F}.\]

\[
\frac{1}{v_{SDW}} m = \pi T \sum_{|q| < \Lambda} \left\langle \frac{m}{\sum_+ + \sum_-} \left( \frac{\epsilon_n^2 + m^2 - \Delta^2}{\sum \sum} \right) \right\rangle, \quad \frac{1}{v_{SDW}} = \ln \frac{1.13 \Lambda}{T_s}.
\]

We begin by presenting explicit formulas for the excitation spectrum, the SDW order parameter, and the free energy. For \( \Delta = 0, \Sigma^2 = \frac{2}{2} \)

\[
\Sigma^2 = (e_n \pm i \delta_{kq})^2 + m^2
\]

and the excitation spectrum consists of four branches with energies \( \pm E_{\pm}(\Delta = 0) \), where

\[
E_\pm(\Delta = 0) = \sqrt{\frac{\epsilon_{kq}^2 + m^2 \pm \delta_{kq}}{2}}.
\]

In Eqs. (3.1) and (3.2),

\[
\delta_{kq} = \frac{\xi_f(k + q) - \xi_f(k)}{2},
\]

\[
\delta_{kq} = -\frac{\xi_f(k + q) + \xi_f(k)}{2} + \frac{\xi_f(k + q) - \xi_f(k)}{2} = \frac{\xi_f(k + q) - \xi_f(k)}{2}.
\]

We remind that \( \delta_{kq} \) describes the mismatch between the shapes of the electron and hole bands and determines their nesting properties in the \( \vec{k} \) direction.

Equation (2.42) for the SDW order parameter \( m \) simplifies to

\[
\frac{1}{v_{SDW}} = 2 \pi T \sum_{|q| < \Lambda} \frac{\Re \left\langle \frac{1}{\sqrt{(\epsilon_n + i \delta_{kq})^2 + m^2}} \right\rangle}{N_F}
\]

and the cutoff \( \Lambda \) can be eliminated in favor of \( T_s \),

\[
\frac{1}{v_{SDW}} = \ln \frac{1.13 \Lambda}{T_s}.
\]
\[
\ln \frac{T}{T_c} = \frac{2\pi T}{e_n > 0} \text{Re} \left( \frac{1}{\sqrt{(\varepsilon_n + i\delta_{\mathbf{k}_0})^2 + m^2}} - \frac{1}{|\varepsilon_n|} \right)
\]

(3.5)

where the summation over \(e_n\) now extends to infinity. Second-order transition temperature \(T = T_s(\delta_{\mathbf{k}_0})\) is obtained by setting \(m = 0\),

\[
\ln \frac{T}{T_s} = \frac{2\pi T}{e_n > 0} \text{Re} \left( \frac{1}{\sqrt{(\varepsilon_n + i\delta_{\mathbf{k}_0})^2 + m^2}} - \frac{1}{|\varepsilon_n|} \right).
\]

(3.6)

The free energy, Eq. (2.43), becomes

\[
\frac{\Delta F(m)}{4N_F} = \frac{m^2}{2} \ln \frac{T}{T_s} - 2\pi T \sum_{e_n > 0} \left( \text{Re} \left( \frac{1}{\sqrt{(\varepsilon_n + i\delta_{\mathbf{k}_0})^2 + m^2}} - \frac{m^2}{2|\varepsilon_n|} \right) \right)
\]

\[
= -\frac{m^2}{2} \ln \frac{1.13\Lambda}{T_s} - 2\pi T \sum_{0 < e_n < \Lambda} \left( \text{Re} \left( \frac{1}{\sqrt{(\varepsilon_n + i\delta_{\mathbf{k}_0})^2 + m^2}} - \frac{m^2}{2|\varepsilon_n|} \right) \right).
\]

(3.7)

Below we consider several special cases for \(\delta_{\mathbf{k}_0}\) (see Fig. 2).

1. Two coaxial circles, \(q = 0\): \(k_F - k_F' = k(k_F - k_F')\),

\[\delta_{\mathbf{k}_0} = \frac{1}{2} \sqrt{v_F} |k_F - k_F'| = \delta_i.\]

(3.8)

For a fixed \(\delta_i\), circular hole and electron FSs survive in the SDW phase when \(m < \delta_i\) [Fig. 2(b)] but come closer to each other as \(m\) increases and merge at \(m = \delta_i\). At larger \(m\) all excitations are gapped [Fig. 2(a)].

2. FS of different shapes, e.g., one circle and one ellipse, cocentered: \(q = 0\) with \(k_F' - k_F' = k(k_F' - k_F') + \Delta k \cos 2\phi\),

\[\delta_{\mathbf{k}_0} = \delta_i + \delta_2 \cos 2\phi, \quad \Delta k = \frac{1}{2} \sqrt{V_F} \Delta \phi.\]

(3.9)

In this case, at small enough \(m\), the FS has a form of two hole and two electron pockets. As \(m\) gets larger, the pockets shrink and eventually disappear.

3. Two circles of different radii, centers shifted by \(q\),

\[\delta_{\mathbf{k}_0} = \delta_i + \frac{1}{2} \sqrt{v_F} |q| = \delta_i + \frac{1}{2} \sqrt{v_F} \cos(\phi - \phi_0),\]

(3.10)

where \(\phi\) and \(\phi_0\) are the directions of \(v_F\) and \(\mathbf{q}\). In this case, when \(m\) increases, gapless excitations survive along a pocket in one region of the \(k\) while excitations with \(-k\) become gapped [Fig. 2(c)]. At large enough \(m\), modified FS appears and excitations with all momenta \(k\) become gapped. This scenario refers to the case when the magnetic ordering occurs at a vector, different from the nesting vector \(Q_0\), producing incommensurate SDW state. It may occur because the electronic system has an option to choose \(q \neq 0\) if it minimizes the energy or because the SDW interaction is peaked at a fixed \(Q \neq Q_0\) for some reason. Note that Eq. (3.5) for SDW order is a magnetic analog of Fulde-Ferrell-Larkin-Ovchinnikov (FFLO) state\(^5\) in a paramagnetically limited superconductor. An incommensurate SDW state at finite dopings has been studied in application to chromium and its alloys\(^57\) and, more recently, to pnictide materials\(^42,60\).

In general, all three terms are present and

\[\delta_{\mathbf{k}_0} = \delta_i + \delta_2 \cos 2\phi + \frac{1}{2} \sqrt{v_F} \cos(\phi - \phi_0).\]

(3.11)

In the figures we use dimensionless parameters that are denoted by a bar. For isotropic and anisotropic FS distortions,

\[\bar{\delta}_{0,2} = \frac{\delta_{0,2}}{2\pi T_s}, \quad \bar{q} = \frac{v_F q}{4\pi T_s},\]

(3.12)

and similarly for other energy variables,

\[\bar{m} = \frac{m}{2\pi T_s}, \quad \bar{\varepsilon} = \frac{\varepsilon}{2\pi T_s}, \quad \bar{\Delta} = \frac{\Delta}{2\pi T_s}.\]

(3.13)

We use different notations for prefactors of \(\cos(\phi - \phi_0)\) and \(\cos 2\phi\) terms to emphasize that they have different origin: \(\delta_2\) is an “input” parameter defined by the elliptic form of the electron FS due to the electronic band structure while \(q\) is adjustable parameter that minimizes the free energy of the system. If the minimum of the free energy corresponds to \(q = 0\), SDW order is commensurate, otherwise SDW order is incommensurate.

In Fig. 3 we show the DOS \(N(\varepsilon)\) for the fixed \(\bar{\delta}_0 = 0.13\) and \(\bar{m} = 0.28\), and different \(\bar{\delta}_2\). For \(\delta_0 = 0\), \(N(\varepsilon)\) vanishes below \(\varepsilon = m - \delta_0\) and has two BCS-type peaks at \(\varepsilon = m \pm \delta_0\). At finite \(\delta_0\), each of the two peaks splits into a “band” bounded by two weaker nonanalyticities separated by \(2\delta_2\). The gap in the DOS behaves as \(m - \delta_0 - \delta_2\) and closes when \(\delta_0 + \delta_2 \approx m\), metallic states forms. The DOS remains the same if we replace the ellipticity parameter \(\delta_0\) by the incommensurability parameter \(\bar{q}\).
FIG. 4. (Color online) The SDW-N transition for commensurate SDW order. The parameters \( \delta_0 \) and \( \delta_2 \) describe the difference between the area of hole and electron pockets and the ellipticity of the electron pocket, respectively. Here and in all subsequent figures dotted lines mark first-order transitions, solid and dashed lines mark second-order transitions. Panel (a): variation in the transition temperature with \( \delta_1 \) for fixed \( \delta_2 \). The transition is second order at small \( \delta_1 \) but becomes first order at larger \( \delta_1 \). At \( \delta_2 = 0 \), the transition becomes first order at \( T_e' = 0.567 T_s \). Panel (b): variation in the transition temperature with \( \delta_2 \) for fixed \( \delta_1 \). \( T_s(\delta_1, \delta_2) \) monotonically decreases with increasing \( \delta_2 \) and vanishes at the same value \( \delta_2 \approx 0.28073 \), independent of \( \delta_0 \).

if we replace the ellipticity parameter \( \delta_2 \) by the incommensurability parameter \( \tilde{q} \) because the angular integral in Eq. (2.45) or Eq. (3.6) over momentum directions on the FS coincides for \( \cos(\phi - \phi_0) \) and \( \cos 2\phi \) terms in \( \delta_{\text{eff}} \) if considered separately. The DOS and \( T_s(\delta_{\text{eq}}) \) change, however, when both \( \delta_2 \) and \( q \) are present simultaneously.

Below we discuss the phase diagram for the pure SDW state to the extend that we will need to analyze potential coexistence between SDW and SC states, which is the subject of this paper.

It is instructive to consider separately the case when SDW order is set to remain commensurate for all \( \delta_{0,2} \) (i.e., \( q = 0 \)) and the case when the system can choose \( q \). In our model, the first case is artificial and just sets the stage to study the actual situation when the value of \( q \) is obtained by minimizing the free energy. However, a commensurate magnetic order may be stabilized in the SDW state, if the interaction \( V_{\text{SDW}} \) is by itself sharply peaked at the commensurate momentum \( Q_0 \).

The results for the case \( q = 0 \) are presented in Fig. 4. In panel (a) we present the results for the transition temperature \( T_s(\delta_0, \delta_2) \) for several values of \( \delta_2 \). All curves show that the transition is second order at high \( T \) and first order at small \( T \). The first-order transition lines [dotted lines in Fig. 4(a)] were obtained by solving numerically the nonlinear equation for \( m \), substituting the result into the free energy [Eq. (3.7)] and finding a location where \( \Delta F(m) = 0 \).

To verify that the transition becomes first order at low \( T \), we expanded the free energy in powers of \( m \) as

\[
\Delta F(m) = \alpha_m m^2 + B m^4 + \cdots \tag{14.14}
\]

and checked the sign of the \( B \) term. The coefficients \( \alpha_m \) and \( B \) are determined from Eq. (3.7),

\[
\alpha_m = \frac{1}{2} \left( \ln \frac{T}{T_s} - 2 \pi T \sum_{\epsilon_n > 0} \Re \left( \frac{1}{\epsilon_n + i \delta_k} \right) - 1 \right),
\]

\[
B = \frac{\pi T}{4} \sum_{\epsilon_n > 0} \Re \left( \frac{1}{\epsilon_n + i \delta_k} \right)^2, \tag{14.15}
\]

where \( \delta_k = \delta_0 + \delta_2 \cos 2\phi \). Solid lines in Fig. 4(a) correspond to \( \alpha_m = 0 \). The N-SDW transition is second order and occurs when \( \alpha_m = 0 \) if \( B > 0 \) but becomes first order and occurs before \( \alpha_m \) becomes negative if \( B < 0 \). We indeed found that for all fixed \( \delta_2 \), for which SDW-N transition is possible, \( B \) changes sign along the line \( \alpha_m = 0 \) and becomes negative at small \( T \). For \( \delta_2 = 0 \), this occurs at \( T_e' = 0.567 T_s \) and \( \delta_0 = 0.17 \).

We point out the following counterintuitive feature in Fig. 4(a). Increase in \( \delta_2 \) reduces the transition temperature at \( \delta_0 = 0 \) and at the same time makes the curve flatter allowing for a larger SDW region along \( \delta_0 \). The transition line becomes completely flat at a critical value \( \delta_{0c} = 0.28073 (2 \pi T_s) \) (see below) when \( T_s(\delta_1, \delta_{0c}) = 0 \). At this point, it spans the interval \( \delta_0 \in [0, \delta_{0c}] \). The existence of the SDW ordered state at \( \delta_2 = \delta_0 \) over a finite range of \( \delta_2 \) despite that the transition temperature is \( 0 \) is a highly nontrivial effect which deserves a separate discussion.\footnote{61}

In Fig. 4(b) we show the transition temperature at fixed \( \delta_0 \), as a function of the ellipticity parameter \( \delta_2 \). As expected, \( T_s(\delta_2) \) monotonically decreases with increasing ellipticity of the electron band. The SDW order exists up to \( \delta_0 = 0 \), at which \( T_s(\delta_{0c}) = 0 \). The value of \( \delta_{0c} \) is independent of \( \delta_0 \) and can be obtained by by taking the limit \( T \to 0 \) in Eq. (3.4) with \( m = 0 \) and rewriting this equation as

\[
\frac{1}{\nu_{\text{SDW}}} = \text{Re} \int_0^\Lambda de \frac{1}{\sqrt{\nu^2 + m_0^2}} = \text{Re} \int_0^\Lambda \frac{2\Lambda}{i \delta_0 + \sqrt{\delta_0^2 - \delta_2}}, \tag{16.16}
\]

The interaction can be eliminated in favor of zero-temperature gap \( m_0 \) at \( \delta_0 = \delta_{0c} = 0 \)

\[
\frac{1}{\nu_{\text{SDW}}} = \int_0^\Lambda de \frac{1}{\sqrt{\nu^2 + m_0^2}} = \text{Re} \frac{2\Lambda}{m_0}, \tag{17.17}
\]

where from Eq. (3.5) we obtain,

\[
m_0 = \frac{2\pi T_s}{2e T_E} = 0.28073 \times (2 \pi T_s) \tag{18.18}
\]

and \( \gamma_E = 0.57722 \) is Euler’s constant. At finite \( \delta_0 \) and \( \delta_2 \), the value of \( m \) at \( T = 0 \) remains equal to \( m_0 \) as long as \( \delta_0 + \delta_2 < m_0 \), and becomes smaller than \( m_0 \) outside this range. The combination of Eqs. (16.16) and (17.17) gives \( \delta_{0c} = m_0 = 0.28073 \times (2 \pi T_s) \), provided that \( \delta_0 < \delta_{0c} \). Another solution \( \delta_0 = 2 \delta_0 m_0 - m_0^2 \) at \( \delta_0 < \delta_{0c} \) corresponds to an unstable state. A similar result has been obtained in the studies of FFLO transition.\footnote{56,62}

The form of \( T_s(\delta_2) \) near \( \delta_{0c} \) can be obtained analytically by rewriting the condition \( \alpha_m = 0 \) in (14.15) as
To analyze the interplay between the appearance of incommensurate SDW order and the sign change in $B$, we again expand the free energy in powers of $m$ but now allow incommensurability parameter $\delta_0$ to be nonzero, i.e., replace in the coefficients in Eq. (3.14), $\delta_k = \delta_0 + \delta c \cos(2\phi)$ with $\tilde{\delta}_k = \delta_k + q \cos(\phi - \phi_0)$. In general, for small $q$,

$$
\alpha_m(\tilde{\delta}_k) = \alpha_0(\delta_k) + \alpha_2(\delta_k)q^2 + \alpha_4(\delta_k)q^4 + O(q^6)
$$

(3.21)

with $\alpha_0(\delta_k)$ given by Eq. (3.15). When $\alpha_4$ and $B$ are positive, the N-SDW transition is second order, and is into a commensurate SDW state when $\delta_0 > 0$ and into an incommensurate SDW state when $\delta_0$ changes sign and becomes negative. If $B$ changes sign while $\alpha_4$ is still positive, the SDW-N transition becomes first order before incommensuration develops.

To understand the phase diagram, it is sufficient to consider small $\delta_0$. Expanding all coefficients in powers of $\delta_0$ we obtain

$$
\alpha_0(\delta_k) = \alpha_{0,0} + \alpha_{0,2}\delta_0^2 + O(\delta_0^4),
$$

(3.22a)

$$
\alpha_2(\delta_k) = \alpha_{2,0} + \alpha_{2,1}\cos 2\phi_0 \delta_0 + O(\delta_0^2),
$$

(3.22b)

$$
\alpha_4(\delta_k) = \alpha_{4,0} + O(\delta_0^4),
$$

(3.22c)

where

$$
\alpha_{0,0} = \frac{1}{2} \left( \ln \frac{T}{T_s} + 2\pi T \sum_{\epsilon_{n,0}} \frac{\delta_0^2 \cos^2 2\phi}{\epsilon_n(\epsilon_n^2 + \delta_0^2 \cos^2 2\phi)} \right) = 0,
$$

(3.19)

integrating explicitly over $\phi$, re-expressing $1/\sqrt{\epsilon_n^2 + \delta_0^2}$ as $(2/\pi) \int_0^\pi dx/(x^2 + \epsilon_n^2 + \delta_0^2)$, and performing the summation over $\epsilon_n$ before the integration over $x$. Carrying out this procedure, we obtain

$$
T_s(\delta_0) = \frac{\delta_0}{\ln(1 - \delta_0/\delta_{2c})},
$$

(3.20)

We see that $T_s$ very rapidly increases at deviations from $\delta_{2c}$. For $\delta_0 = 0.9974\delta_{2c}$, $\delta_{2c} = 0.28$, Eq. (3.20) yields $T_s(\delta_2) = 0.3T_s$, in good agreement with Fig. 4(a).

Also, one can easily show that at $T=0$ fermionic excitations in the SDW state are all gapped when $m_0 > \delta_0 + \delta_2$. When $\delta_0 + \delta_2 > m_0$, the SDW state possess Fermi surfaces and gapless fermionic excitations.

We next consider the case when the system is free to choose between commensurate and incommensurate SDW orders and may develop incommensurate order to lower the free energy. In Fig. 5 we show the transition temperature $T_s(\delta_0)$ for fixed $\delta_2$. We found that, for all $\delta_2$, first-order transition is overshadowed by a transition into an incommensurate SDW state. For $\delta_2 = 0$, incommensurability develops exactly where $B$ changes sign and the transition into incommensurate SDW state remains second order for all $\delta_0$. For $\delta_2 > 0$, incommensurability develops before $B$ changes sign, and the transition into incommensurate SDW state remains second order over some range of $\delta_0$ but eventually becomes first order at large $\delta_0$ and low $T$. The full phase diagram also contains a transition line (not shown in Fig. 5) separating already developed commensurate and incommensurate SDW orders.

![Figure 5](link)

**Figure 5.** Same as in Fig. 4 but when the system is allowed to choose between commensurate and incommensurate SDW orders. Solid lines are second-order transition lines into a state with a commensurate SDW order and dashed lines are second-order transition lines into an SDW state with an incommensurate SDW order (the magnetic analog of FFLO state). For all $\delta_2 > 0$, incommensurability occurs before the commensurate transition becomes first order (the onset of incommensuration and first-order transition coincide for $\delta_2 = 0$). Observe that incommensuration develops at progressively smaller $\delta_2$ as $\delta_2$ increases and $T_s(\delta_2)$ decreases but the range of $\delta_0$ over which incommensurate SDW order exists actually increases with increasing $\delta_2$.

To understand the phase diagram, it is sufficient to consider small $\delta_2$. Expanding all coefficients in powers of $\delta_2$ we obtain

$$
\alpha_2(\delta_k) = \alpha_{2,0} + \alpha_{2,1}\cos 2\phi_0 \delta_0 + O(\delta_0^2),
$$

(3.22b)

$$
\alpha_4(\delta_k) = \alpha_{4,0} + O(\delta_0^4),
$$

(3.22c)

where

$$
\alpha_{0,0} = \frac{1}{2} \left( \ln \frac{T}{T_s} + 2\pi T \sum_{\epsilon_{n,0}} \frac{\delta_0^2}{\epsilon_n(\epsilon_n^2 + \delta_0^2)} \right),
$$

(3.23a)

$$
\alpha_{2,0} = \frac{1}{4} \frac{\epsilon_n^2 - \delta_0^2}{(\epsilon_n^2 + \delta_0^2)^3},
$$

(3.23b)

$$
\alpha_{2,1} = \frac{3}{2} \frac{\epsilon_n^2 - \delta_0^2}{(\epsilon_n^2 + \delta_0^2)^3},
$$

(3.23c)

$$
\alpha_4 = \frac{3}{16} \frac{\epsilon_n^4 - 10\delta_0^2\epsilon_n^2 + 5\delta_0^4}{(\epsilon_n^2 + \delta_0^2)^5}.
$$

(3.23d)

We see from Eq. (3.22) that for $\delta_2 = 0$, $B$ and $\alpha_2(\delta_k)$ change sign simultaneously, at the point where $\alpha_{2,0} = -\alpha_{2,0} = 0$. However, when $\delta_2 \neq 0$, $\alpha_2(\delta_k)$ changes sign before $B$ becomes negative because $\alpha_2(\delta_k)$ contains a term linear in $\delta_2$, whose prefactor can be made negative by adjusting $\phi_0$. This explains why in Fig. 5 incommensuration begins while $B$ is still positive. Also, we verified that near the onset points for incommensuration, $\alpha_4(\delta_k) > 0$, i.e., in this range the transition into incommensurate SDW is second order. At larger $\delta_0$, the incommensurate transition eventually becomes first order.

### IV. SDW+SC STATE, NUMERICAL ANALYSIS

In the next two sections we look at potential coexistence of SDW and the $s^+$ or $s^{++}$ states, when the system is doped...
and the SDW order is suppressed. The superconducting $T_c$ is doping independent, so at some doping SDW and SC transition temperatures cross. Near this point, the two orders either support or suppress each other and either coexist or are separated by a first-order transition.

In this section we present numerical results in the extended range of temperatures and dopings and in the next section we corroborate them with analytical consideration in the vicinity of the crossing point, when both order parameters are small, and at $T=0$.

A. Coexistence with $s^\pm$ state

We look first at the $s^\pm$ state. In this case the system of coupled self-consistency equations for $\Delta$ and $m$ is obtained from Eqs. (2.41)–(2.43) by taking $\Sigma^\pm_2 = (E_n \pm i\delta_{\text{D}})^2 + m^2$ and $E_n = \sqrt{\epsilon_n + \Delta^2}$.

\[
\ln \frac{T}{T_c} = 2\pi T \sum_{\epsilon_n>0} \text{Re} \left( \frac{(E_n + i\delta_{\text{D}})E_n}{\sqrt{(E_n + i\delta_{\text{D}})^2 + m^2}} - \frac{1}{|E_n|} \right),
\]  

(4.1a)

\[
\ln \frac{T}{T_f} = 2\pi T \sum_{\epsilon_n>0} \text{Re} \left( \frac{1}{\sqrt{(E_n + i\delta_{\text{D}})^2 + m^2}} - \frac{1}{|E_n|} \right),
\]  

(4.1b)

We remind that $T_c$ is the transition temperature for the pure SC state and $T_f$ is the transition temperature for the pure SDW state at $\delta_{\text{D}}=0$.

These equations are solved numerically to find all possible states $(\Delta, m)$ and their energies evaluated using Eq. (2.43). The main results for this part are presented in Figs. 6–12.

1. Commensurate SDW state

Figure 6 shows the results for the case when SDW order is set to be commensurate (i.e., $q=0$) and the FSs are either coaxial circles [panel (a)] or of different shapes with equal $k_F$ (panel b). In the first case, $\delta_2=0$ and $\delta_0 \neq 0$, and in the second case $\delta_0=0$ and $\delta_2 \neq 0$. We see that in both cases pure SDW and SC states are separated by a first-order transition. We verified that in both cases fermionic excitations in the SDW state are fully gapped at $T=0$ and thus there are no Fermi surfaces. From this perspective, the results presented in Fig. 6 are consistent with the idea that coexistence requires the presence of the Fermi surfaces in the SDW state. However, we will see next that the situation in the cases when both $\delta_0$ and $\delta_2$ are nonzero is more complex.

This is demonstrated in Fig. 7 which shows the phase diagram for $T_c/T_f=2$ as a function of $\delta_2$ for a set of fixed $\delta_0$ [panels (a1)–(a3)] and as a function of $\delta_0$ for a set of fixed $\delta_2$ [panels (b1)–(b3)]. For all cases, pure SDW state is fully gapped at $T=0$, so naively one should not expect a coexistence state. However, as is evident from the figure, the phase diagram does involve the coexistence phase, which can be either at low $T$ (including $T=0$), or near $T=T_c$, depending on the parameters. In particular, as $\delta_2$ in panels (a) or $\delta_0$ in panels (b) increase, the coexistence state first appears at low $T$ while at higher $T$ the pure SDW and SC states are still separated by a first-order transition [panels (a1) and (b1)]. Then the coexistence region grows and extends up to $T=T_c$ [panels (a2) and (b2)]. At even larger $\delta_2$ or $\delta_0$, SDW and SC states are separated by the first-order transition at low $T$ but the coexistence phase still survives near $T_c$.

In Fig. 8 we show the phase diagram for $\delta_2=0.2$ and $T_c/T_f=5$ together with the plots of SDW and SC order parameters and the free energy. We see the same behavior as in Fig. 7(a2)—there is a coexistence phase for all $T$ up to $T_c$. In
Fig. 8. (Color online) (a) Same as in Fig. 7(b) but for $T_s/T_c = 5$. [(b) and (c)] SDW and SC gaps, in units $\bar{m}$ and $\bar{\Delta} = \Delta / 2\pi T_c$, and the free energy (b) as functions of $\bar{\delta}_0$ along the line $T/T_c = 0.2$, and (c) as functions of temperature for $\bar{\delta}_0 = 0.17$.

Fig. 9 we show the changes in the quasiparticle DOS at low $T = 0.17T_c$ as the system evolves from the SDW state to the SC state via the coexistence region.

Finally, in Fig. 10, we show the zero-temperature phase diagram in variables $\bar{\delta}_0$ and $\bar{\delta}_2$ for $T_s/T_c = 2$ and $T_s/T_c = 5$, together with the locus of points, where $T_s(\bar{\delta}_0, \bar{\delta}_2) = T_c$. The phase diagram was obtained by numerically solving Eq. (4.1) and evaluating the free energy at $T/T_c = 0.02$. This phase diagram corroborates the results of Figs. 7 and 8—the zero $T$ behavior in panels (a) and (b) in Fig. 7 is obtained by taking either horizontal or vertical cuts in Fig. 10. In particular, we see from Fig. 10 that the transformation between panels (a2) and (a3) of Fig. 7 is such that the coexistence region at $T = 0$ first moves to the left, shrinks, and disappears at $\bar{\delta}_2 \approx 0.24$. Similarly, in panels (b), the coexistence range shrinks to a point at $\bar{\delta}_0 \approx 0.16$ and at larger $\bar{\delta}_0$ the transition between SDW and SC phases at $T = 0$ becomes first order. In the next section we present the results of complimentary analytical studies of the phase diagram at $T = 0$ and near $T_c$. These results are in full agreement with the numerical analysis in this section.

Observe that for $T_s/T_c = 5$ the left boundary of the coexistence region is located very close to the line $\bar{\delta}_0 + \bar{\delta}_2 = m_0$ (dashed line in Fig. 10, $\bar{\delta}_0 + \bar{\delta}_2 = 0.28073$), at which gapless excitations and Fermi surfaces appear in the SDW state. For this $T_s/T_c$, the coexistence region at $T = 0$ virtually coincides with the region where SDW state has a Fermi surface. However, for smaller $T_s/T_c = 2$ (Fig. 7; left panel in Fig. 10), coexistence clearly occurs already in the parameter range where SDW excitations are all gapped. The coexistence for $T_s/T_c = 2$ is therefore not the result of the “competition for the Fermi surface” but rather the consequence of the fact that the system can gain in energy by reducing the SDW order parameter (still keeping all fermionic excitations gapped) and creating a nonzero SC order parameter. The gain of energy in this situation can best be interpreted as the consequence of the effective attraction between the two orders.
appears below $T_s$. The SDW + SC phase appears only in a small region near $T_c$. At low $T$ the system still undergoes a first-order transition between commensurate SDW and SC states. For larger $T_c/T_\gamma$ (weaker SC interaction) the coexistence region widens and extends down to $T=0$. The $q=0$ SDW state has the lowest energy at $T=0$ for $\bar{\delta}_s \leq 0.195$.

2. Commensurate vs incommensurate SDW state

One of the results of our consideration so far is that, if we keep an SDW order commensurate, a finite region of SDW + SC phase appears only when both $\delta_0$ and $\delta_2$ are nonzero. If we allow the system to choose the ordering momentum of the SDW state, the coexistence region widens and appears even if we set $\delta_2=0$. We illustrate this in Fig. 11, where we plot the phase diagram at $\bar{\delta}_s=0$ for two different values of $T_\gamma/T_c$. In agreement with Fig. 5, at $T<T_\gamma$, the system chooses an SDW state with a nonzero $q$. We see that, in this situation, there appears a region where SC state coexist with an incommensurate SDW state. The coexistence region widens up when the ratio $T_\gamma/T_c$ increases and for large enough $T_\gamma/T_c$ extends down to $T=0$. In Fig. 12 we set $\bar{\delta}_s$ to be nonzero ($\bar{\delta}_s=0.2$) and allowed the system to choose $q$ which minimizes the free energy. The results are quite similar to the case when $q=0$. We see that the SDW and SC orders do coexist in the parameter range which extends from the crossing point down to $T=0$. The width of the coexistence region widens a bit when we allow the system to choose $q$, but qualitatively, the behavior in Figs. 8 and 12 is the same. Note, in our two-band model, the ellipticity of the electron FS breaks the rotational symmetry and favors the direction of $q$ along the ellipse’s major axis, see Eq. (3.22b).

To summarize, SDW and SC$^{++}$ phases do coexist in a range of finite dopings but the width of the coexistence region depends on the amount of ellipticity of the electron band and the ratio of $T_\gamma/T_c$. At larger $T_\gamma/T_c$ the width of the coexistence region increases for fixed $\delta_0$ and there is optimal $\bar{\delta}_s$ at which the width is the largest. The fact that the system can lower the energy by making SDW order incommensurate also acts in favor of coexistence but qualitatively the picture remains the same as in the case when $q$ is set to be zero.

B. Minimal coexistence with $s^{++}$ state

We next look at the SC state with gaps of the same signs on two FSs. Such states seem unlikely for pnictides because they require a negative sign of the interband pair hopping term. Still, it would be interesting to investigate consequences of attractive SC interaction between electron and hole bands.

The expressions for $\Sigma_\perp$ in this case is slightly more complicated and less illuminating than those for $s^{++}$ state, although quite similar, and so are the self-consistency equations, which we do not write here but which are obtained from Eqs. (2.41)-(2.43) in a way completely analogous to Eqs. (4.1). We first present the results for $\bar{\delta}_s=0$, Fig. 13. We found that coexistence region does not appear even if we allow SDW order to become incommensurate. There are commensurate and incommensurate SDW phases on the phase diagram, and SC$^{++}$ phase, but the transition between SC and SDW phases remains first order. In other words, the appearance of gapless excitations in the SDW phase due to incommensuration at large $\bar{\delta}_s$ does not seem to favor a mixed superconducting and magnetic state, in sharp contrast to the case of $s^{--}$ SC, where incommensuration induces coexistence, see Fig. 11(b).

FIG. 11. (Color online) The phase diagram for $\bar{\delta}_s=0$, when the system can choose the value of $q$. Commensurate SDW order appears below $T_\gamma=0.56T_c$ and leaves some parts of the FS un-gapped, allowing for coexisting SC order. (a) $T_\gamma/T_c=3$. The SDW + SC phase appears only in a small region near $T_c$. At low $T$ the system still undergoes a first-order transition between commensurate SDW and SC states. (b) For larger $T_\gamma/T_c=5$ (weaker SC interaction) the coexistence region widens and extends down to $T=0$. The $q=0$ SDW state has the lowest energy at $T=0$ for $\bar{\delta}_s \leq 0.195$.

FIG. 12. (Color online) Same as in Fig. 8(a) but now we allow the system to choose the value of $q$. The phase diagram from Fig. 8 is shown by dashed lines. A finite $q$ emerges below a particular $T$ and moves the coexistence region to larger $\bar{\delta}_s$ together with the SDW-N transition. This broadens the coexistence region and slightly changes the shape of $T_\gamma(\bar{\delta}_s)$ inside the magnetic dome.

FIG. 13. (Color online) The phase diagram for a conventional $s^{++}$ SC order parameter, at $\bar{\delta}_s=0$, and varying $\bar{\delta}_s$. We allow the system to choose $q$. The SDW+SC state does not appear, even when SDW order becomes incommensurate.
We begin with the GL analysis near the point where \( T_s(\delta_0, \delta_2)=T_c \). Near this point, both the SDW and SC order parameters are small and we can expand the free energy, Eq. \( (2.43) \), to the fourth order in \( m \) and \( \Delta \) and compare different phases. For simplicity, in this section we assume that the SDW order parameter is commensurate. An extension to a finite \( q \) complicates the formulas but does not change the outcome.

The expansion of the free energy, Eq. \( (2.43) \) in powers of \( m \) and \( \Delta \) yields

\[
\mathcal{F} = \alpha_{\Delta} \Delta^2 + \alpha_m m^2 + \lambda \Delta^4 + B m^2 + 2 C \Delta^2 m^2. \tag{5.1}
\]

where \( \mathcal{F} = \Delta F(m, \Delta)/(4 N_g) \). Coefficients \( \alpha_{\Delta}, \alpha_m, A \), and \( B \) in Eq. \( (5.1) \) are identical for both \( s^- \) and \( s^+ \) SC states:

\[
\alpha_{\Delta} = \frac{1}{2 \ln T_c^ - T_c}, \tag{5.2}
\]

\[
\alpha_m = \frac{1}{2} \left( \frac{\ln T_c^ - 2 \pi T \sum_{n>0} \left< \frac{\delta_k^2}{\epsilon_n^+ + \delta_k^2} \right>}{\epsilon_n^+} \right) \tag{5.3}
\]

and

\[
A = \frac{\pi T}{4} \sum_{n>0} \frac{1}{\epsilon_n^+}, \tag{5.4}
\]

\[
B = \frac{\pi T}{4} \sum_{n>0} \frac{\epsilon_n^2 - 3 \delta_k^2}{\epsilon_n^+ (\epsilon_n^+ + \delta_k^2)^2}. \tag{5.5}
\]

The difference between \( s^- \) and \( s^+ \) SC orders appears only in the coefficient \( C \). For \( s^+ \) state we have

\[
C_{(+)} = \frac{\pi T}{4} \sum_{n>0} \left< \frac{\epsilon_n^2 - \delta_k^2}{\epsilon_n^+ (\epsilon_n^+ + \delta_k^2)^2} \right> \tag{5.6}
\]

while for \( s^+ \)

\[
C_{(++)} = \frac{\pi T}{4} \sum_{n>0} \left< \frac{3 \epsilon_n^2 + \delta_k^2}{\epsilon_n^+ (\epsilon_n^+ + \delta_k^2)^2} \right> \tag{5.7}
\]

Note that, although both \( C \) coefficients are positive, this does not preclude coexistence in Eq. \( (5.1) \), and we find below that the sign of parameter \( \chi = AB - C^2 \) is more important for coexistence. We will demonstrate that since \( C_{(++)} > C_{(+)} \), \( \chi \) is positive for a broader range of parameters in \( s^+ \) state than that in \( s^+ \) state. In fact, \( \chi \) remains always negative in \( s^+ \) state. Below we will use the notation that \( \chi > 0 \) corresponds to an effective attraction between the two orders.

The free energy, Eq. \( (5.1) \), has two local minima, corresponding to pure states, when one of the order parameters is identically equal to zero.

1. A pure SC state, defined by \( m=0 \) and \( \partial \mathcal{F}/\partial \Delta = 0 \), has the free energy and SC order parameter...
is reduced because SDW instability is suppressed when nesting becomes nonperfect. Superconducting \( \alpha_n \) is not affected by \( \delta_k \) and eventually wins over SDW. Second, coefficients \( B \) and \( C \) evolve with \( \delta_k \) and, as a result, the sign of \( \chi = AB - C^2 \) depends on values of \( \delta_0 \) and \( \delta_2 \).

The GL expansion is applicable only in the vicinity of points at which the temperatures of the SDW-N and SC-N transitions coincide \( T_{c0}(\delta_k) = T_c \). This condition together with Eq. (3.6) establish the relation between \( \delta_0 \) and \( \delta_2 \) at which one needs to compute the parameters \( B \) and \( C \).

1. \( s^\pm \) superconductivity

To get an insight on how \( \chi \) evolves with \( \delta_{k_{\parallel}} \), we first assume that \( T_j/T_c \) is only slightly larger than one \( (T_j/T_c = 1 + \delta) \), in which case \( T_j(\delta_{k_{\parallel}}) \approx T_c \) at small \( \delta_0 \) and \( \delta_2 \), and we can expand \( A \), \( B \), and \( C \) in powers of \( \delta_0 \) and \( \delta_2 \). Specifically, we have from Eq. (3.6),

\[
\delta = \frac{7\zeta(3)}{4\pi^2 T_c^2} \left( \delta_0^2 + 2\delta_2^2 \right) - \frac{0.663}{m_0^2} \left( \delta_0^2 + 2\delta_2^2 \right),
\]

where \( \zeta(3) \) is a Riemann-Zeta function. Collecting terms up to the fourth order in the expansion, we obtain

\[
\chi = \frac{1}{32\pi^4 T_c^8} \left( s_1(\delta_0^2)^2 + s_2(\delta_2^2)^2 \right),
\]

where

\[
s_1 = 5 \left( \sum_{n \geq 0} \frac{1}{(2n + 1)^3} \right) \left( \sum_{n \geq 0} \frac{1}{(2n + 1)^7} \right),
\]

\[
s_2 = 9 \left( \sum_{n \geq 0} \frac{1}{(2n + 1)^5} \right)^2.
\]

The sums are expressed in terms of the Riemann-Zeta function \( \zeta(3) \), \( \zeta(5) \), and \( \zeta(7) \) and give \( s_1 = 5.261 \) and \( s_2 = 9.082 \). Substituting \( \delta_{k_{\parallel}} = \delta_0 + \delta_2 \cos 2\phi \) and averaging over momentum direction \( \phi \) on the FSs, we obtain

\[
\chi \approx \frac{1}{32\pi^4 T_c^8} \left( -3.820\delta_0^2 + 6.703\delta_2^2 - 0.297\delta_0^4 \right).
\]

We see that for \( \delta_0 = \delta_2 = 0 \), \( \chi = 0 \), i.e., for a perfect nesting the system cannot distinguish between first-order transition and SDW+SC phase. This result, first noticed in Ref. 29, implies that the phase diagram is quite sensitive to the interplay between \( \delta_0 \) and \( \delta_2 \). We see from Eq. (17) that in the two limits when either \( \delta_0 = 0 \) or \( \delta_2 = 0 \), \( \chi < 0 \), i.e., the transition is first order. This agrees with the numerical analysis in the previous section. We emphasize that in both limits, a small SDW order, which we consider here, still preserves low-energy fermionic states near the modified FSs. Fermions near these FSs do have a possibility to pair into \( s^\pm \) state. However, SDW+SC state turns out to be energetically unfavorable. We particularly emphasize that the ellipticity of electron dispersion is not sufficient for the appearance of the SDW+SC phase near \( T_c \).

When both \( \delta_0 \neq 0 \) and \( \delta_2 \neq 0 \), there is a broad range
we computed the transition between SDW and SC states occurs via the coexistence region. For \( \chi < 0 \), the present GL analysis is invalid.

Equation (5.18) has to be combined with the equation for \( T_c(\delta_0, \delta_2) = T_c' \), and the boundaries in Eq. (5.18) set the critical values of \( \delta_0 \) and \( \delta_2 \) as functions of \( T_c/T_c' \). Combining Eqs. (5.18) and (5.14), we obtain that coexistence occurs for

\[
0.765 < \frac{\delta_2}{\delta_0} < 4.689, \quad (5.18)
\]

where \( \chi > 0 \) and the transition from a pure SDW phase to pure a SC phase occurs via an intermediate phase where the two orders coexist. This also agrees with the numerical analysis (see Figs. 8 and 10).

To verify that this result holds at larger values of \( \delta_0 \) and \( \delta_2 \), we computed \( \chi \) without expanding in \( \delta_0 \). We plot the resulting phase diagram in Fig. 15. The result is qualitatively the same as Eq. (5.17): for \( \delta_0 = 0 \) or \( \delta_2 = 0 \), \( \chi < 0 \) and the transition between SDW and SC states is of first order while when both \( \delta_0 \) and \( \delta_2 \) are nonzero, there exists a region where \( \chi > 0 \) and the transition from SDW to SC state occurs via an intermediate SDW+SC phase.

2. \( s^{++} \) superconductivity

We performed the same calculations for a conventional, sign-preserving \( s \)-wave superconductivity. The key difference with the \( s^{+} \) case is that now \( \chi = AB - C^2 \) is nonzero already when \( \delta_0 = \delta_2 = 0 \). Substituting \( A \) and \( B \) from Eqs. (5.4) and (5.5) and \( \delta_0 \) from Eq. (5.7) we obtain

\[
\chi(\delta_0 = 0) = -\frac{7(3)}{128\pi^3 T_c^4} < 0. \quad (5.20)
\]

The implication is that, for small \( \delta_0 \) and \( \delta_2 \), \( \chi \) remains negative and the transition between SDW and SC states is first order. This result was first obtained by Fernandes et al. in Ref. 29. These authors also argued, based on their numerical analysis of the free energy, that there is no SDW+SC phase for \( s^{++} \) gap even when \( \delta_0 = \delta_2 \) are not small. We analyzed the sign of \( \chi \) for larger \( \delta_0 \) and \( \delta_2 \) using our analytical formulas and confirmed their result. In Fig. 16 we show the behavior of \( \chi(\delta_0, \delta_2) \) at the transition point \( T_c(\delta_0, \delta_2) = T_c' \) for three representative cases: \( \chi(\delta_0, 0), \chi(0, \delta_2), \) and \( \chi(\delta_0, \delta_0) \). In all cases, when \( B > 0 \) (e.g., our GL analysis is valid) \( \chi(\delta_0, \delta_2) \) remains negative.

We caution, however, that the absence of coexistence between \( s^{++} \) SC and SDW states within GL model does not imply that the two states are always separated by a first-order transition. GL analysis is only valid near \( T_c(\delta_0, \delta_2) = T_c' \), when both orders are weak. The situation at lower \( T \) has to be analyzed without expanding in \( m \) and \( \Delta \). And, indeed, we did find a small coexistence region \( T = 0 \), see Fig. 14.

B. Zero-temperature limit

We consider only the case of \( s^{\pm} \) SC and the limit when relevant \( \delta_0 \) and \( \delta_2 \) are small, i.e., when \( T_c/T_c' = 1 + \delta_0 \) and \( \delta_0 \ll 1 \). We compare energies for pure SDW and SC state and for the coexistence state and find the region where the coexistence state is energetically favorable.

For this, we first verified that, at small \( \delta_0 \) and \( \delta_2 \), the values of SDW and SC order parameters at \( T = 0 \) remain the same as at \( \delta_2 = \delta_0 = 0 \), i.e., \( m = m_0 = 0.28073 \times (2\pi T_c) \) and \( \Delta = \Delta_0 = m_0 T_c/T_c' \). These values only change at large enough \( \delta_0 \) and \( \delta_2 \), e.g., \( m \) changes when \( \delta_0 + \delta_2 > m_0 \).

The free energies of pure SDW and SC states for \( m, \Delta > \delta_0 + \delta_2 \) can be straightforwardly evaluated at \( T = 0 \) by replacing the frequency sums in Eq. (2.43) by integrals. We obtain

\[
F(m) = -\frac{m^2}{4} + \frac{\delta_0^2}{2} + \frac{\delta_2^2}{4} + m^2 \ln \frac{m}{m_0}, \quad (5.21)
\]
SUPERCONDUCTIVITY AND SPIN-DENSITY WAVES IN...

\[ \mathcal{F}(\Delta) = -\frac{\Delta^2}{4} + \frac{\Delta^2}{2} \ln \left( \frac{\Delta}{\Delta_0} \right). \]  

(5.22)

These free energies have minima at \( m = m_0 \) and \( \Delta = \Delta_0 \), respectively. At the minima,

\[ \mathcal{F}(m_0) = -\frac{m_0^2}{4} + \frac{\delta_0^2}{2} + \frac{\delta_0^2}{4}. \]

\[ \mathcal{F}(\Delta_0) = -\frac{\Delta_0^2}{4} = -\left( \frac{T_c}{T_s} \right)^2 \frac{m_0^2}{4}. \]  

(5.23)

Observe that \( \mathcal{F}(\Delta_0) < \mathcal{F}(m_0) \) when \( T_c = T_s \). This is the consequence of the fact that SDW magnetism is destroyed by doping and ellipticity while superconductivity is unaffected.

Comparing \( \mathcal{F}(m_0) \) and \( \mathcal{F}(\Delta_0) \), we find that the first-order transition between pure SDW and SC states occurs at

\[ m_0^2 \delta = \delta_0^2 / 2. \]  

(5.24)

If there is no intermediate coexistence phase, the SDW state is stable for \( \delta_0 \geq \sqrt{m_0^2 \delta - \delta_0^2 / 2} \) while SC state is stable for larger values of \( \delta_0 \).

We next determine when the intermediate state appears at \( T = 0 \). For this we expand the free energy near the SDW and SC states in powers of \( \Delta \) and \( m \), respectively. We obtain near the SDW state,

\[ \mathcal{F}(m, \Delta) = \mathcal{F}(m_0) + a_1 \Delta^2 + b_1 \Delta^4 \]  

(5.25)

and near the SC state

\[ \mathcal{F}(m, \Delta) = \mathcal{F}(\Delta_0) + a_2 m^2 + b_2 m^4. \]  

(5.26)

We verified that \( b_1 \) and \( b_2 \) are positive while \( a_1 \) and \( a_2 \) can be either sign. The key issue is what are the signs of \( a_1 \) and \( a_2 \) at the point where \( \mathcal{F}(m_0) = \mathcal{F}(\Delta_0) \). We found that, to leading order in \( \delta \), \( a_1 = a_2 = a \) at this point and \( a \) is given by

\[ a = \frac{\delta_0^2}{6} (1 - 8z + 7z^2), \quad z = \frac{\delta_0^2}{2m_0 \delta \eta}. \]  

(5.27)

Note that to obtain \( a \) we had to expand to order \( \delta \). By virtue of Eq. (5.24), \( \delta_0 = \sqrt{m_0 \delta \eta / (1 - z)} \), i.e., we have to consider \( z \leq 1 \).

When \( a \) is positive, both pure states are stable and there is a first-order transition between them. When \( a < 0 \), the pure SDW and SC states are already unstable at the point where \( \mathcal{F}(m_0) = \mathcal{F}(\Delta_0) \), which implies that when we vary \( \delta_0 \) at a fixed \( \delta \), there is a range of \( \delta_0 \) around \( \delta_0 = \sqrt{m_0 \delta \eta / (1 - z)} \) in which the coexistence state has a lower energy than the pure states. From Eq. (3.1) we see that \( a > 0 \) when \( z < 1 / 7 \) while \( a < 0 \) for \( 1 / 7 < z < 1 \). In terms of \( \delta_0 \), this implies that the transition at \( T = 0 \) is first order between pure states when \( \delta_2 < 0.535m_0 \delta \eta \) while at larger \( \delta_0 \), pure SDW and SC phases are separated along \( \delta_0 \) line by the region of the coexistence phase. The width of the coexistence phase initially increases as \( \delta_0 \) increases but then begins to shrink and vanishes when \( \delta_0 \) approaches \( \delta_0 = 1.414m_0 \delta \eta / (5) \) (\( z \) approaches one from below). At this point, the coexistence region shrinks to a point \( \delta_0 = 0 \). At larger \( \delta_0 \), SC state has lower energy than the SDW state for all values of \( \delta_0 \).

If we keep \( \delta_0 \) fixed but vary \( \delta_1 \), the coexistence range appears at \( \delta_1 = +0 \) (\( z = 1 \)) and exists up to \( \delta_1 = 0.926m_0 \delta \eta / (z = 1 / 7) \). At larger \( \delta_0 \) (\( z < 1 / 7 \)), there is a first-order transition between pure SDW and SC states.

C. Phase diagram

We now combine the results of GL analysis near the crossing point and at \( T = 0 \) into the phase diagrams. For definiteness, we set \( \delta = T / T_s - 1 \) to be small and consider the set of phase diagrams in variables \( T \) and \( \delta_0 \) for different fixed \( \delta_2 \). The results of this section has to be compared with the phase diagrams presented in panels (a1)–(a3) in Fig. 7, see also Fig. 10.

From the analysis in the preceding two sections, we found five critical values of \( \delta_2 \): two are obtained from the GL analysis of the range of the coexistence phase, and are given by Eq. (5.19), two are critical values at which the coexistence phase first appears and then disappears at \( T = 0 \), and the last one is the maximum value of \( \delta_0 \) at which \( T_c(\delta_0 = 0, \delta_2) = T_s \). From Eq. (5.14) this value is \( \delta_0 = 1.739m_0 \delta \eta \). Arranging these five values from the smallest to the largest, we obtain the following set of phase diagrams at small \( \delta \).

(a) For \( \delta_2 < 0.535m_0 \delta \eta \), there is no intermediate phase, and pure SDW and SC transitions are separated by a line of a first-order transition. The line is tilted toward smaller \( \delta_0 \) at smaller \( T_1 \); it originates at \( \delta_0 = \sqrt{m_0 \delta \eta / (1 - 0.5 \delta_2^2 (m_0^2 \delta \eta))]^{1 / 2} \) at \( T = T_s \) and ends up at \( \delta_0 = \sqrt{m_0 \delta \eta / (1 - 0.5 \delta_2^2 (m_0^2 \delta \eta))]^{1 / 2} \).

(b) For \( 0.535m_0 \delta \eta < \delta_2 < 0.826m_0 \delta \eta \), the intermediate phase appears near \( T = 0 \) and extends to some \( T < T_c \). At larger \( T \), the transition remains first order. This behavior is consistent with the panel (a1) in Fig. 7.

(c) For \( 0.826m_0 \delta \eta < \delta_2 < 1.414m_0 \delta \eta \), the intermediate phase occupies the whole region \( T < T_c \). This behavior is consistent with the panel (a2) in Fig. 7.

(d) For \( 1.414m_0 \delta \eta < \delta_2 < 1.663m_0 \delta \eta \), SC state wins at \( T = 0 \) for all \( \delta_0 \). There is phase transition at finite \( T \). The transition is first order between pure SDW and SC state at smaller \( T \) but the coexistence phase still survives near \( T_c \). This behavior is consistent with the panel (a3) in Fig. 7.

(e) For \( 1.663m_0 \delta \eta < \delta_2 < 1.739m_0 \delta \eta \), the coexistence phase near \( T_s \) disappears and the transition becomes first order along the whole line separating SDW and SC states.

(f) For \( \delta_2 > 1.739m_0 \delta \eta \), \( T_c(\delta_0, \delta_2) \) becomes smaller than \( T \) for all \( \delta_0 \) and the system only develops a SC order.

This behavior is also totally consistent with Fig. 10: all different phase diagrams are reproduced if we take horizontal cuts at different \( \delta_2 \). We see therefore that numerical and analytical analysis is in full agreement with each other.

The only result of numerical studies not reproduced in small \( \delta \) analytical expansion is the existence of a range of \( \delta_2 \) where the transition between the SDW phase and the coexistence phase is second order while the transition between the SC phase and the coexistence phase is first order, see Fig. 10. To reproduce this effect in analytical treatment, we would have to expand to the next order in \( \delta \). Note in this regard that it is evident from Fig. 10 that the width of the range where one transition is first order and another is second order shrinks as \( T_s / T_c \) decreases.

VI. PARTIAL SDW STATE

In previous sections we considered the situation when the splitting between hole and electron FSs is small. We now consider how the phase diagram is modified if in some $k$-regions hole and electron FSs are quite apart from each other (after we shift the hole FS by $Q_0$). Such regions are far from nesting and we make a simple assumption that they are not affected by SDW. We then split the FS into nested parts where commensurate SDW state exists and a SC order can exist as well, and non-nested parts, where only SC order is possible. We present this schematically in Fig. 17. The nested parts lie in some intervals of angles $\phi$ with total circumference $\Delta \phi$ and have weight $N_{SDW}/N_{total}=1$ ($\Delta \phi/2\pi = N_{SDW}/N_{total}$).

The free energy and the self-consistency equations then can be written as sums of the two contributions. The first sum is over the FS part that has only SC order parameter and in the second sum we integrate over part of the FS with both orders,$^{37}$

$$\frac{\Delta F (\Delta, m)}{4N_F} = \frac{\Delta^2}{2} \ln \frac{T}{T_c} + N_{SDW} \frac{m^2}{2} \ln \frac{T}{T_s} - 2\pi T \sum_{e_n > 0} (1 - N_{SDW}) \left[ \sqrt{\frac{\Delta^2}{2} - |\epsilon_n|} - \frac{\Delta^2}{2 |\epsilon_n|} \right]$$

$$- 2\pi T \sum_{e_n > 0} \int_{\Delta \phi} \frac{d\phi}{2\pi} \left[ 1 + \frac{1}{2} \frac{\partial \Sigma_+}{\partial \Delta} + \frac{\partial \Sigma_-}{\partial \Delta} - \frac{\Delta}{|\epsilon_n|} \right]$$

$$\times \text{Re} \left[ \frac{1}{2} (\Sigma_+ + \Sigma_-) - |\epsilon_n| - \frac{\Delta^2}{2 |\epsilon_n|} - \frac{m^2}{2 |\epsilon_n|} \right].$$  (6.1)

FIG. 17. (Color online) A partially gapped SDW state, where only a fraction $N_{SDW}$ of the electron and hole FSs is nested. On the remaining parts the dispersions $\xi_j$ and $\xi_c$ are very different. The SDW state appearing below $T_s$ gaps excitations only in the shaded/boxed areas [see Fig. 2(d)] while on the rest of the FSs the dispersions are close to the original $\xi_j$ and $\xi_c$. The SC state below $T_c$ does not compete with SDW in non-nested regions but competes with SDW state in the nested (boxed) regions.

FIG. 18. (Color online) (a) The phase diagram for $s^\pm$ superconductivity and SDW order parameter existing only in boxed regions of the FS in Fig. 17, with the relative width $N_{SDW}$. We manually set the doping dependence of $N_{SDW}$ to be $N_{SDW} = 0.8 - 0.4(\delta_0/0.3)$ and neglected the effect of this variation in $N_{SDW}$ on $T_s$. Observe that SC and SDW orders coexist in a wide range of $\delta_0$ and $T_c$. [(b) and (c)] the order parameters, $\Delta$ and $m$, and the free energy, $F$, as functions of $\delta_0$ at a constant temperature, $T/T_c = 0.2$ (b) and as functions of $T_c$ at a constant $\delta_0 = 0.13$ (c). As a function of $\delta_0$, SDW order parameter starts decreasing when SC order appears and then jumps to zero and the system becomes a pure SC.

$$\Delta \ln \frac{T}{T_c} = \frac{2\pi T}{e_n > 0} \left[ 1 - N_{SDW} \left[ \sqrt{\frac{\Delta^2}{2} - |\epsilon_n|} - \frac{\Delta^2}{2 |\epsilon_n|} \right] \right]$$

$$+ 2\pi T \sum_{e_n > 0} \int_{\Delta \phi} \frac{d\phi}{2\pi} \text{Re} \left[ \frac{1}{2} \frac{\partial \Sigma_+}{\partial \Delta} + \frac{\partial \Sigma_-}{\partial \Delta} - \frac{\Delta}{|\epsilon_n|} \right],$$

$$N_{SDW} \ln \frac{T}{T_c} = 2\pi T \sum_{e_n > 0} \int_{\Delta \phi} \frac{d\phi}{2\pi} \text{Re} \left[ \frac{1}{2} \frac{\partial \Sigma_+}{\partial m} + \frac{\partial \Sigma_-}{\partial m} - \frac{m}{|\epsilon_n|} \right].$$  (6.2)

The self-consistency Eqs. (6.2) and (6.3) are obtained by minimization of the functional $\Delta F$, $\partial (\Delta F) / \partial \Delta = 0$ and $\partial F / \partial m = 0$, and these expressions reduce to previous formulas (2.41)–(2.43) for $N_{SDW} = 1$.

We find that the results are very similar to what we found within the approximation of a small FS splitting. The typical picture is shown in Fig. 18.

The only differences from Fig. 8 in this case are the co-existence of SC and SDW states already at zero doping $\delta_0 = 0$ and weak first-order transition to purely SC state. We also analyzed $s^\pm$ SC order and again found a much weaker tendency for co-existence, similar to Fig. 14.

VII. CONCLUSIONS

To conclude, we presented a general theoretical description of the interplay between itinerant SDW and SC orders in
two-band metals. Within the mean-field approach we derived coupled self-consistency equations for the order parameters and the expression for the free energy, which is necessary to determine the stability of different phases.

We considered the FS geometry with one-hole and one-electron bands of different shapes (a simplified FS geometry for Fe pnictides) and investigated the phase diagrams and the stability of the SDW+SC states for: (a) different gap structures of the SC state, Figs. 8 and 10 vs Fig. 14; (b) variations in the relative strength of SDW and SC interactions, Figs. 10 and 11; (c) ellipticity of electron pockets, Figs. 7, 8, and 10; and (d) incommensurability of SDW order, Figs. 11 and 12. We considered the case when the transition temperature to pure SDW state, $T_s$, is higher than the critical temperature $T_c$ of a pure SC state. In the opposite case, $T_s < T_c$, the SC state develops first and suppresses SDW state.

We found that the SC $s^\pm$ state with extended $s$-wave symmetry has much stronger affinity with the SDW state than the traditional $s^\pm$ state. A coexistence region of $s^\pm$ SC state with SDW is tiny and the coexistence is anyway very weak in terms of energy gain compared to the pure SDW state. The transition from the pure SDW state to the pure SC state is always first order, Fig. 14. For $s^\pm$ gap, there is a stronger inclination toward coexistence with SDW state due to effective attraction between the two orders. We found that, depending on the interplay between different effects (e.g., ellipticity and doping), the transition between SDW and SC orders is either first order or continuous, via the intermediate SDW+SC phase, in which both order parameters are non-zero, Figs. 6–8,63.

We note that the coexistence region gets larger with increased strength of the SDW interaction relative to its SC counterpart, described by the ratio $T_s/T_c$. Thus generally we should see better coexistence between SDW and SC states, if $T_s$ is increasingly larger than $T_c$, Fig. 10.

Our results are in disagreement with a common belief that, because SDW and SC states compete for the Fermi surface, the SDW+SC state should emerge when a pure SDW state next to the boundary of the coexistence region still has a modified Fermi surface at $T=0$ and should not emerge when fermionic excitations in the pure SDW phase are fully gapped at zero temperature. We found that the key reason for the existence of the mixed SDW+SC state is the “effective attraction” between the SDW and SC orders while the presence or absence of the Fermi surface in the SDW state at $T=0$ matters less. Specifically, we found cases when SDW and SC orders do coexist even when fermionic excitations in the pure SDW phase are fully gapped at $T=0$, Fig. 10(a), and we also found, for $s^\pm$ pairing, that there might be no coexistence down to $T=0$ even when the pure SDW phase has a Fermi surface, Fig. 14.

The phase diagrams for $s^\pm$ gap are quite consistent with the experimental findings in pnictides. For example, first-order transition in Fig. 6 looks very similar to phase diagram of 1111 materials (La,Sr)FeAs, where FSs are more cylindrical. The coexistence region in Fig. 8 correlates well with doped 122 materials based on BaFe$_2$As$_2$, where hole and electron FSs are less nested. And Fig. 10 shows that one can get both SDW+SC phase and first-order transitions for the same SC state and the same family of materials. Our key result is that the way the doping is introduced into the sample will determine the nature of the FS changes and the path it will take in the $(\delta_\parallel, \delta_\perp)$ plane: whether through a first-order transition or through a coexistence region. In other words, we argue that there is strong correlation between how exactly FSs evolve upon doping and whether or not SD and SC states coexist.

The final remark. In the literature, there exists a notion of “homogeneous” and “inhomogeneous” coexistence of SC and SDW orders. The latter is a metastable state when the two orders exist in different spatial parts of the material. What we emphasize is that the other kind, homogeneous coexistence of SC and SDW orders in real space, is in fact inhomogeneous in momentum space: the SC and SDW orders dominate excitation gaps on different parts of the FS.

APPENDIX: ELECTRON AND HOLE DISPERSION FOR SMALL FS SPLITTING

In this appendix, we discuss in detail the approximation we used for the dispersions of holes and electrons for the case when the splitting between hole and electron FSs is small.

SDW and SC orders mix $c$ fermions with momenta $k$ and $f$ fermions with momenta $k+q$. The generic expressions for the two dispersions are

$$\xi_c(k) = \mu_c - \frac{(k+q)^2}{2m_c} = \frac{\mu_c + \mu_f}{2} - \frac{k^2}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) - \frac{kq}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) + \frac{\mu_c - \mu_f}{2} - \frac{k^2}{4} \left( \frac{1}{m_c} - \frac{1}{m_f} \right) + \frac{kq}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right)$$

$$\xi_f(k) = \mu_f - \frac{(k+q)^2}{2m_f} = \frac{\mu_c + \mu_f}{2} - \frac{k^2}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) - \frac{kq}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) + \frac{\mu_c - \mu_f}{2} + \frac{k^2}{4m_c(m_c-m_f)} + \frac{kq}{2m}$$

(A1)

When the two FSs are circles of nonequal size, $m_c = m_f$, we have $(\mu_c, m_c) = (\mu_f, m_f)$ and $m_c = \neq m_f$ and $\mu_c = \mu_f$. The approximation we used in the text implies that...
\[ \xi_f(k + q) = \frac{(k + q)^2}{2m_f} - \mu_f = \frac{k^2}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) + \frac{kq}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) - \frac{\mu_c + \mu_f}{2} + \frac{\mu_c - \mu_f}{2} - \frac{k^2}{4} \left( \frac{1}{m_c} - \frac{1}{m_f} \right) + \frac{kq}{4} \left( \frac{3}{m_c} - \frac{1}{m_f} \right) \]

\[ = \frac{k^2}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) + \frac{kq}{4} \left( \frac{1}{m_c} + \frac{1}{m_f} \right) - \frac{\mu_c + \mu_f}{2} + \frac{\mu_c - \mu_f}{2} + \frac{k_F^2}{4m} (m_c - m_f) + \frac{k_F q}{2m} \]  

(A2)

Introducing \( \delta_{kq} \) and \( \xi_{kq} \) defined in Eq. (2.30), we obtain

\[ \delta_{kq} = \frac{\mu_c - \mu_f}{2} + \frac{k_F^2}{4m} (m_c - m_f) + \frac{k_F q}{2m} - \frac{v_F}{m} (k_F^2 - k_F^2 - q). \]  

(A3)

We emphasize that, within this approximation, \( \xi_{kq} \) and \( \delta_{kq} \) are two independent variables, one depends on the deviation along the FS in the transverse direction and another depends on the angle along the FS. When \( m_{f_x} \neq m_{f_y} \), the derivation remains the same but \( \delta_{kq} \) acquires an additional term with the difference between \( m_{f_x} \) and \( m_{f_y} \) (the \( \cos 2\phi \) term).

V. Cvetkovic and Z. Tesanovic, EPL 85, 37002 (2009).

A d-wave symmetry gap presumably lies in between these two cases as some parts of the nested hole and electron FSs will have the gaps of the same sign while other parts will have the opposite signs (Ref. 29).
